Abstract

Hundreds of factors have been proposed to explain asset returns during the past two decades, a situation which Cochrane (2011) has dubbed “a zoo of new factors”. In this paper, we develop a Bayesian approach to explore the space of possible linear factor models in the “zoo”. We conduct an extensive search for promising models using a set of 83 candidate factors based on the literature and applying the methodology to thousands of individual stocks. Despite the large number of factors that have been proposed, our results show that (i) only a handful of factors appear to explain the returns on individual stocks; (ii) from these, the only factor that is consistently selected over time is the market excess return; and (iii) other factors which are selected during certain periods are not those in widely used multi-factor models.

Keywords: Factor selection, Bayesian variable selection, Seemingly Unrelated Regressions

1. Introduction

Which factors should enter a linear factor model, and what kind of fundamental, pervasive, non-diversifiable risks do they represent? This is a crucial question that has haunted researchers for a long time. As more data have become available, and computational costs have decreased, the number of proposed factors to explain asset returns has increased significantly. For example, Harvey et al. (2016) document more than three hundred factors that have been proposed in the literature, most within the last two decades, a situation which Cochrane (2011) has dubbed “a zoo of new factors”.

However, it is doubtful that all of these factors really matter in asset pricing; it is more likely that some of them are redundant, or proxies for the same kind of fundamental risk, whilst many (or even most) may just be a product of data mining. The huge number of factors that have been identified in empirical studies is a challenge for both practitioners and academics, in particular, considering that earlier empirical studies suggested five to six factors, and that most prominent and widely used models such as the ones proposed by Fama & French (1992) (henceforth, FF3), Carhart (1997), Pastor & Stambaugh (2003), Chen & Zhang (2010) (henceforth, CZ), Hou et al. (2015a) (henceforth, HXZ) and Fama & French (2015) (henceforth, FF5) have five or less factors. Some recent studies, such as Harvey & Liu (2016), Green et al. (2017), Yan & Zheng (2017), and Feng et al. (2017), have investigated large numbers of factors proposed in the literature in order to identify independent information about average stock returns.

In this study we develop a Bayesian approach to explore the space of possible linear factor models and identify the most promising models to explain asset returns. We propose an estimation method for the posterior probabilities of models, i.e. sets of factors, rather than testing individual factors with respect to pre-specified models such as the Fama-French five factor model. With so many candidate factors within the factor “zoo”, the number of possible models is astronomical, making model comparison a challenging task. For example, the total number of models is over 1 billion with 30 factors because the number of possi-

---

1 They also provide a taxonomy of these factors, refer to their Table 1. Also see Green et al. (2017) and McLean & Pontiff (2016), which summarize hundreds of factors proposed in the literature.

2 See Chordia et al. (2017) and Kewei et al. (2017).

ble models with $K$ factors is $2^K$. We develop a novel method that evaluates the space of all possible models, which would be computationally prohibitive in the conventional framework even for moderate number of factors.

For this purpose, we introduce a Bayesian variable selection method that explores the model space, i.e. posterior probabilities of the most promising models. For the $K$ candidate predictor variables, a vector of the joint posterior distribution of $\gamma = (\gamma_1, \ldots, \gamma_K)$ of dummy variable $\gamma_j$ can be defined to represent whether the $j$-th predictor should be included in the model. A non-hierarchical model is employed, where the prior distribution of the regression coefficients (the factor sensitivities or $\beta$s in a multi-factor asset pricing model) is independent from that of $\gamma_j$s. The introduction of $\gamma$ makes it possible to explore the space of possible models, even with large numbers of factors. Our contribution in terms of methodology can be summarized as follows. First, we propose a simple approach by specifying independent priors for $\gamma$ and $\beta$, extending the univariate regression model proposed by Kuo & Mallick (1998) to the multivariate seemingly unrelated regressions (SUR) model. Second, we derive a sequential algorithm to estimate the regression coefficients (factor sensitivities) of each response variable (each asset) using the Gibbs sampler\(^4\). This provides an efficient way to estimate the model even for larger numbers of test assets and factors, which allows the application of the method to sets of large numbers of individual stocks, instead of portfolios\(^5\).

Our Bayesian approach overcomes the multiple comparison problem raised by Harvey et al. (2016) and others. When a large number of signals are tested to investigate cross-sectional asset returns, some signals will appear to be statistically significant by random chance even if they have no genuine predictive ability. Our procedure allows us to simultaneously assess the most promising models within the space of all possible models, instead of statistical inference based on a “single” test, and therefore, all individual signals are evaluated together as (argued) in Sullivan et al. (1999, 2001). The Bayesian framework differs from the frequentist perspective of Harvey et al. (2016) who propose a t-statistic greater than 3 for any new factor. Our approach can be applied to thousands of individual assets together with hundreds of potential factors, and thus does not need to reduce dimensions of test assets by forming portfolios (Lo & Mackinlay, 1990; Ferson

---

\(^5\)In terms of methodology, our approach is mostly related to the literature on variable selection in multivariate regression models, of which the SUR model is a special case, see Brown et al. (1998), Smith & Kohn (2000), Hall et al. (2002), Wang (2010), Ando (2011), Ouysse & Kohn (2010), and Puelz et al. (2017).
et al., 1999; Berk, 2000). The complex cross-sectional dependencies can be considered in this framework as all possible combinations of factors are evaluated. Multi-collinearity problems that become serious when the number of independent variables increase, can be avoided because our approach is to select the best possible models from the posterior probability of $\gamma^6$.

In the empirical tests, we consider a set of 83 candidate asset pricing factors that have been proposed in the literature. In addition to the market factor (excess market return), we compute 82 tradable factors by sorting stocks into value-weighted decile portfolios based on various firm characteristics and variables that have been proposed in the literature, and calculating the return difference between the top and bottom decile portfolios. We apply our Bayesian variable selection methodology to all available stocks in different sub-sample periods from 1980 to 2016. We also consider 20 different sets of portfolios of stocks, comprising over 300 individual portfolios.

Our empirical results with individual stocks suggest that only a small number of factors (5 to 6) are important to explain the individual stock returns. The only factor that is consistently selected over time is the market excess return. Moreover, the other factors that are selected in this study are not those that have been widely used in the literature, i.e, factors such as those in the FF3, FF5, CZ and HXZ models, but include short-term reversal, change in 6-month momentum, change in number of analysts following stocks, and industry concentration. These results are robust to different specifications of the priors about the factor sensitivities.

In comparison with some recent studies such as Green et al. (2017) and Barillas & Shanken (2017), our results show a smaller number of relevant factors. For example, Green et al. (2017) use a set of 94 firm characteristics in Fama-MacBeth regressions and show that 12 characteristics are important to explain returns on stocks over the period 1985-20147. Barillas & Shanken (2017) find evidence supporting a six-factor model including the the market return, investment,

---

6Although Green et al. (2017) and Feng et al. (2017) evaluate the effects of the multi-collinearity problem carefully, this problem does not disappear in the conventional regression with the large number of independent variables that are possibly cross-correlated.

7The 12 characteristics identified in the study are book-to-market, cash, change in the number of analysts, earnings announcement return, one-month momentum, change in six-month momentum, number of consecutive quarters with earnings higher than the same quarter a year ago, annual R&D to market cap, return volatility, share turnover, volatility of share turnover, and zero trading days. The authors also find that this number reduces to only 2 (industry-adjusted change in employees and number of earnings increases) since 2003, with the returns to hedge portfolios that attempt to exploit this predictability becoming insignificant.
profitability, size, book-to-market, and momentum factor. Other recent studies with a large number of candidate factors, such as Harvey et al. (2016) and Feng et al. (2017), have also found that the market factor is the most important one, with a possible role for profitability and investment.

The main difference from these results lies in how these factors are selected. The factors in our study are selected from a larger set of factors, using an approach that considers all factors simultaneously. Therefore, our results do not suffer from the multiple comparison problem (Harvey et al., 2016). On the other hand, most other studies in the literature identify additional factors relative to arbitrary sets of factors, or even without considering other possible factors. When the entire set of factors is searched for the best model, a set of a smaller number of factors is required.

One interesting result is that the intercept term is not selected to explain returns on individual stocks, indicating that the models with high posterior probabilities explain well the returns of individual stocks. Therefore, our method can be an alternative to the traditional asset pricing tests such as the Fama & MacBeth (1973) procedure or the Gibbons et al. (1989) test. These tests suffer from problems that reduce their power, and require grouping of individual stocks into portfolios, which introduces biases if the variable used to sort stocks into portfolios is related to the factors in the model. In contrast, our procedure considers many factors simultaneously and can naturally be applied when the number of assets is larger than the number of time-series observations.

Our work also differs markedly from previous studies that apply a Bayesian approach to select asset pricing factors, such as Ericsson & Karlsson (2003), Ouysse & Kohn (2010), Puelz et al. (2017) and Barillas & Shanken (2017). These studies have focused on a smaller number of candidate factors, with a relatively small number of portfolios as test assets. Although the Bayesian approach proposed by Barillas & Shanken (2017) is designed to test individual asset pricing models, the number of candidate factors is limited due to its computational costs. In contrast, our methodology allows us to explore a larger model space with many possible factors, using thousands of individual stocks simultaneously, therefore bypassing the problem of using as test assets portfolios that may be related to the factors by construction. In fact, when we apply our methodology to 20 different sets of portfolios (300 portfolios in total), we find a very strong dependence between the portfolio formation criteria and the posterior probability of factors. For example, when portfolios are formed on firm characteristics, models with the fac-
tors formed on these characteristics are selected with high posterior probability.8

The rest of this paper is organized as follows. We introduce the model and briefly discuss the estimation method in Section 2. The explanation of the data set and factor construction follow in Section 3. Section 4 provides the main empirical results of the paper, as well as robustness tests and comparison with previous studies. Section 5 concludes. The Bayesian estimation of the SUR model is reviewed in Appendix A. Appendix B contains detailed explanations of the variable selection model and its estimation. Appendix C provides the full list of firm characteristics used in this study, and the associated references.

2. Methodology

Consider $N$ assets and $K$ predictor variables (factors) over $T$ periods. The factor model is a multivariate linear regression with $N$ equations:

$$r_i = X\beta_i + e_i, \quad i = 1, \ldots, N$$ (1)

where, for each asset $i$, $r_i$ is the $T \times 1$ vector of excess returns, $X$ is the matrix of factors with dimension $T \times K$, $\beta_i = (\beta_{i,1}, \ldots, \beta_{i,K})'$ is a vector of unknown regression coefficients (factor sensitivities), and $e_i$ is a $T \times 1$ vector of disturbances.9 If the error terms are contemporaneously cross-correlated, the system of regressions above is a special case of the Seemingly Unrelated Regressions (SUR) model, where the predictor variables are the same for all equations.10

The system can be stacked in a single equation $\tilde{r} = \tilde{X}\tilde{\beta} + \tilde{e}$ in the following

---

8This is related to the concerns expressed by Lo & Mackinlay (1990), Ferson et al. (1999), Berk (2000), Roll (1977) and Lewellen et al. (2010) in the context of bias in asset pricing tests using portfolios related to the factors. A similar conclusion is reached by Harvey & Liu (2016). They argue that dispersion in portfolios is largely driven by a few portfolios that are dominated by small stocks, which leads asset pricing tests to identify factors that can explain these extreme portfolios.

9To avoid ambiguity, throughout this article we use the subscripts $i$ and $j$ for assets and predictor variables, respectively.

10The SUR model, introduced by Zellner (1962), consists of $N$ regression equations, each with $T$ observations, which are linked solely through the covariance structure of error terms at each observation, i.e. errors are contemporaneously correlated but not autocorrelated.
\begin{align*}
[r_1] & = [X \ 0 \ \cdots \ 0] [\beta_1] + [e_1] \\
[r_2] & = [0 \ X \ \cdots \ 0] [\beta_2] + [e_2] \\
& \vdots \\
[r_N] & = [0 \ 0 \ \cdots \ X] [\beta_N] + [e_N],
\end{align*}

where \( \bar{e} = (e'_1 \quad e'_2 \ \cdots \quad e'_N)' \), and \( \mathbb{E}(\bar{e}\bar{e}') = \Omega = \Sigma \otimes I_T \).

Bayesian inference in the SUR model can be carried out in a relatively straightforward manner, see for example Giles (2003). Since our variable selection procedure will rely on a Markov Chain Monte Carlo (MCMC) approach using the Gibbs sampler, we start by reviewing the estimation of the SUR through this approach. Suppose \( \bar{e} \sim N(0, \Sigma \otimes I_T) \) and the following prior distributions for \( \bar{e} \) and \( \Sigma \):

\begin{align*}
\bar{\beta} & \sim N(b_0, B_0) \\
\Sigma & \sim IW(\nu_0, \Phi_0),
\end{align*}

where \( IW(\nu_0, \Phi_0) \) denotes the inverted-Wishart distribution with \( \nu_0 \) degrees of freedom and parameter matrix \( \Phi_0 \). With these choices, it can be shown that the conditional posterior distributions required for the Gibbs sampler are as follows\(^\text{11}\):

\begin{align*}
\bar{\beta}|\Sigma, r & \sim N(b_1, B_1) \\
\Sigma|\bar{\beta}, r & \sim IW(\nu_1, \Phi_1),
\end{align*}

where

\begin{align*}
b_1 & = (B_0^{-1} + \bar{X}'\Omega^{-1}\bar{X})^{-1}(B_0b_0 + \bar{X}'\Omega^{-1}\bar{r}) \\
B_1 & = (B_0^{-1} + \bar{X}'\Omega^{-1}\bar{X})^{-1} \\
\nu_1 & = \nu_0 + T, \quad \Phi_1 = \Phi_0 + S.
\end{align*}

In the above, \( S \) is the matrix of cross-products of the residuals, that is, if \( E = [e_1 \ldots e_N] \), then \( S = E'E \). We also note that \( \Omega^{-1} = \Sigma^{-1} \otimes I_T \).

The approach above may be computationally intensive if the number of equations is large, since it requires multiplication and inversion of large matrices. For example, \( \bar{X} \) has dimension \( NT \times NK \) and \( \Omega^{-1} \) has dimension \( NT \times NT \). By

\(^{11}\)The full derivation of all the conditional distributions required for the Gibbs sampler estimation is provided in Appendix A.
sampling each $\beta_i$ conditionally on the remaining $\beta_j, j \neq i$ and $\Sigma$, we derive an alternative and quicker approach for a large panel. Let $\tilde{\beta}_{-i}$ denote the full vector $\tilde{\beta}$ omitting $\beta_i$. Assume that

$$\beta_i | \tilde{\beta}_{-i}, \Sigma \sim N(b_{0,i}, B_{0,i}).$$

Then, $\beta_i | \tilde{\beta}_{-i}, \Sigma, r \sim N(b_{1,i}, B_{1,i})$, with

$$b_{i,j} = (B_{0,j}^{-1} + \sigma^{ii}X'X)^{-1} (B_{0,j}b_{0,j} + \sigma^{ii}X'r_j),$$

$$B_1 = (B_{0,i}^{-1} + \sigma^{ii}X'X)^{-1},$$

where $\sigma^{ii}$ denotes the $(i, i)$ element of $\Sigma^{-1}$ and $r_j$ is suitably defined based on a partition of the systems of equations, see Appendix A.2. Note that the expressions above depend only on the smaller matrices $X$ and $\Sigma$. In the Gibbs sampler, each $\beta_i$ can be generated in random order.

2.1. Bayesian Variable Selection in the SUR Model

There is a vast literature focusing on Bayesian variable selection in linear models with a single response variable, see for example George & McCulloch (1993, 1997); Kuo & Mallick (1998); Dellaportas et al. (1999); Hans et al. (2007); Clyde & George (2004); O’Hara & Sillanpää (2009). For a single regression equation, Bayesian variable selection is typically done by first introducing a vector $\gamma = (\gamma_1, \ldots, \gamma_K)'$ of dummy variables, where if $\gamma_j = 1$, the $j$-th predictor is included in the model, and conducting inference on the posterior distribution of $\gamma$. Since the vector of $K$ dummy variables indicates $2^K$ possible models, comparison of all possible models becomes computationally infeasible for even moderate numbers of regressors. In this case, MCMC methods provide a fast way to obtain consistent estimates of model probabilities.

Variable selection in the multivariate regression models (of which the SUR model is a special case) has been the subject of a number of studies, mostly focusing on generalizations of the hierarchical Bayesian model of George & McCulloch (1993)\footnote{One of the first examples of this approach is Brown et al. (1998). Smith & Kohn (2000) introduced a Bayesian hierarchical model which considers variable selection by explicitly allowing the possibility that some coefficients are equal to zero. Hall et al. (2002) consider a hierarchical Bayesian model related to Smith & Kohn (2000) to choose style factors in models for global stock returns. Wang (2010) also follows the hierarchical setup of George & McCulloch (1993),}, which defines the distribution of $\beta$ conditionally on $\gamma$. This is done by specifying a “slab and spike” mixture distribution which places a spiked prior on
zero for $\beta_j \mid \gamma_j = 0$ and a slab or flat prior on $\beta_j \mid \gamma_j = 1$. One disadvantage of this approach is that it often requires data-dependent tuning of the hyper-parameters.

In this study, we assume a priori independence between $\beta_j$ and $\gamma_j$ which requires no tuning and extend the univariate regression model proposed by Kuo & Mallick (1998) to the case of the SUR model with common regressors.

We generalize the method proposed by Kuo & Mallick (1998) to the SUR model as follows. Let $X_\gamma$ represent the matrix $X$ where each column has been multiplied by the corresponding $\gamma_j$. Then we can write the model with variable selection as $r_i = X_\gamma \beta_i + e_i, i = 1, \ldots, N$, or stacking the $N$ equations as before,

$$\tilde{r} = \tilde{X}_\gamma \tilde{\beta} + \tilde{e},$$

where $\tilde{X}_\gamma$ is defined analogously as before. Equivalently, we define a new variable $\theta_i = \beta_i \odot \gamma$, where $\odot$ represents element-wise multiplication. The system can then be represented by $\tilde{r} = \tilde{X} \tilde{\theta} + \tilde{e}$. Analysis of the posterior distribution of $\tilde{\theta}$ would be useful to understand which variables are important for each equation.

To derive the conditional distributions required for the Gibbs sampler, we need to specify the prior distribution for $\gamma$. We follow Kuo & Mallick (1998) and set independent priors as $\gamma_j \sim B(1, \pi_j), j = 1, \ldots, K$. Therefore, the prior distribution of $\gamma$ is given by

$$f(\gamma) = \prod_{j=1}^{K} \pi_j^{\gamma_j} (1 - \pi_j)^{1-\gamma_j}.$$  

Note that, conditional on a known value of $\gamma$, the model reduces to a SUR with the corresponding predictors for which $\gamma_j = 1$. Therefore, using the same prior distributions for $\tilde{\beta}$ and $\tilde{\Sigma}$ in Equation (3), the conditional distributions for $\tilde{\beta}$ and $\tilde{\Sigma}$ are those given in equation (4), with $\tilde{X}$ replaced by $\tilde{X}_\gamma$. Thus we have

$$\tilde{\beta} \mid \gamma, \Sigma, r \sim N(b_1, B_1)$$

$$\tilde{\Sigma} \mid \gamma, \tilde{\beta}, r \sim IW(v_1, \Phi_1),$$

where

\[
\begin{align*}
    b_1 & = (B_0^{-1} + X'_\gamma \Omega^{-1} X_\gamma)^{-1}(B_0 b_0 + X'_\gamma \Omega^{-1} \tilde{r}) \\
    B_1 & = (B_0^{-1} + X'_\gamma \Omega^{-1} X_\gamma)^{-1} \\
    \nu_1 & = \nu_0 + T, \quad \Phi_1 = \Phi_0 + S.
\end{align*}
\]

As before, if the number of equations is large, we can sample each \( \beta_i, i = 1, \ldots, N \) in turn from \( \beta_i | \tilde{\beta}_{-i}, \gamma, \Sigma, \tilde{r} \sim N(b_{1,i}, B_{1,i}) \), where

\[
\begin{align*}
    b_{1,i} & = (B_{0,i}^{-1} + \sigma^{ii} X'_\gamma X_\gamma)^{-1}(B_{0,i} b_{0,i} + \sigma^{ii} X'_\gamma r_i) \\
    B_{1,i} & = (B_{0,i}^{-1} + \sigma^{ii} X'_\gamma X_\gamma)^{-1}.
\end{align*}
\]

To generate \( \gamma \), we use the Gibbs sampler to generate each value of \( \gamma \) as in Kuo & Mallick (1998). The relevant conditional posterior probability of \( \gamma_j = 1 \) for the SUR model is given by

\[
P(\gamma_j = 1 | \gamma_{-j}, \tilde{\beta}, \Sigma, \tilde{r}) = \left( 1 + \frac{1 - \pi_j}{\pi_j} \exp(-0.5 \text{Tr}(\Sigma^{-1}(S^1_j - S^0_j))) \right)^{-1}, \quad (6)
\]

where \( S^1_j \) and \( S^0_j \) represent the matrices of residuals when \( \gamma_j = 1 \) and \( \gamma_j = 0 \), respectively. Each \( \gamma_j \) can be generated, preferably in random order, using the expression above\(^{13}\).

### 2.2. Prior Distributions

The most important prior distribution is the one for \( \tilde{\beta} \). As discussed by O’Hara & Sillanpää (2009), the MCMC algorithm might not mix well in the \( \gamma \) space if the prior for \( \tilde{\beta} \) is too vague. The reason for this is that, when a particular \( \gamma_j = 0 \), the \( \beta_{ij}, i = 1, \ldots, N \) are sampled from the full prior conditional distribution. In this case, it may be difficult for the model to transition between \( \gamma_j = 0 \) and \( \gamma_j = 1 \), since the generated \( \beta_{ij} \) will be unlikely to be in the region where \( \theta_{ij} \) has higher posterior probability.

We propose a few choices for the priors on \( \tilde{\beta} \). The first is \( \tilde{\beta} \sim N(0, cI) \). This choice reflects a complete lack of knowledge about the predictors, both in terms of which predictors should enter the model as well as regarding the dependence structure of the regression coefficients. A second possibility is \( \tilde{\beta} \sim \)

\(^{13}\)An alternative approach is to apply a Metropolis-within-Gibbs step of the type suggested by Brown et al. (2002), see also George & McCulloch (1997).
\(N(0, c(\bar{X}'\bar{X})^{-1})\), which makes the prior covariance structure equal to the design covariance structure, as suggested by Zellner (1971). A final possibility is to center each \(\beta_i\) around their OLS or maximum likelihood estimate, *i.e.* \(\beta_i \sim N((X'X)^{-1}X'r_i, c_i(X'X)^{-1})\). All of these choices can be made less informative by increasing \(c\). Note that the first component of each \(\beta_i\) is for the alpha of each regression. The intercept is included as a factor because there is no guarantee that the factors we test in this study can fully explain individual stock returns.

The standard choice for the prior for \(\Sigma\) is to set \(\nu_0 = N\) and \(\Phi_0 = I\). Another possibility is to choose the parameters so that the prior variance will be equal to a given number, which may come from our knowledge of the problem. For the prior of \(\pi_j\), the prior probability that predictor \(j\) is included in the model, we choose an equal probability of \(\frac{1}{2}\) for all factors. This prior reflects the lack of knowledge about the inclusion of the predictors, and implies that any model, regardless of its possible number of combinations, has an equal prior probability of \(\frac{1}{2^K}\). Prior information regarding predictors that researchers include in the model can be incorporated by letting \(\pi_j = 1\). For example, if we want to reflect a prior belief that the market factor should always be included, we can set the corresponding \(\pi_j\) equal to 1.

2.3. **Comparison with other variable selection models**

The method we propose has two main differences compared to other approaches. The first one is that we do not follow the hierarchical structure as in Brown *et al.* (1998); Smith & Kohn (2000); Ouyssse & Kohn (2010); Wang (2010); Ando (2011); Puelz *et al.* (2017). Our non-hierarchical structure results in a simple method for variable selection in SUR models, with the advantage that it does not require complex tuning of the hyper-parameters.

It is possible to make inference about which variables matter for each asset (equation) by summarizing the posterior distribution of \(\theta_i = \beta_i \odot \gamma\). Thus, by focusing on finding a single set of predictors for the \(N\) equations, we identify common pricing factors in the multi-factor models. Other studies such as Wang (2010) and Puelz *et al.* (2017) propose methods that can identify different sets of predictors for each equation.

3. **Data and Factor Construction**

3.1. **Factor Returns and Their Statistical Properties**

For the candidate factors, we use 82 firm characteristics that have been tested by Green *et al.* (2017) for the sample period from January 1980 to December
2016, a total of 37 years (444 months). Factor returns are calculated by the
difference between the value-weighted returns on the highest and lowest decile portfolios. We use all available U.S. common stocks from the CRSP and Com-
pustat databases for the calculation of factor returns. As in Green et al. (2017),
characteristics are updated on a monthly basis using the available accounting in-
formation. In addition to these 82 factors, we also consider the excess market return. Since we also consider the intercept as a factor for the purposes of our
Bayesian variable selection procedure, the total number of factors is 84. Due to
differences in data availability, different factors are available for different sub-
sample periods.

Table 1 reports basic descriptive statistics for the factors used in this study. For
each factor, we calculate and report statistics using all the available stocks. We
also report Dependent False Discovery Rate (DFDR) p-values using the method
of Benjamini & Yekutieli (2001), which takes into account the fact that multiple
tests are being run simultaneously. The factors with a DFDR p-value less than
0.05 are shown in bold, and the corresponding t-statistic includes an asterisk.

The average returns on the factors based on well-known characteristics such as
mve (market cap), bm (book-to-market ratio) and mom12m (12-month momen-
tum) are in line with numbers reported on the literature. Despite the differences in
the factor return calculation and the sample period, the average factor returns are
similar to those of Green et al. (2017). It is noteworthy that only 6 of the 83 fac-
tors are significant when the DFDR p-values are considered, despite the fact that
27 factors have t-statistics higher than 2.0 in absolute value, reflecting the much
higher burden of significance when multiple testing is taken into account. These
factors are acc (working capital accruals), chesho (change in shares outstanding),
chinv (change in inventory), invest (capital expenditures and inventory), nanalyst

---

14 We thank Jeremiah Green for making his SAS code available online. The firm characteris-
tics that have too many missing values or whose deciles are not meaningful are excluded. The
excluded characteristics are convind (convertible debt indicator), divi (dividend initiation), divo
(dividend omission), dy (dividend yield), ipo (new equity issue), nincr (number of earnings in-
creases), rd (R&D increase), rd_mve (R&D to market capitalization), rd_sale, secured (secured
debt), securedind (secured debt indicator) and sin (Sin stocks). The exclusion of these 12 firm
characteristics, however, does not affect our main results because the intercept is not selected for
the explanation of individual stocks.

15 We apply the same procedure for all characteristics, and thus average return difference may
be positive (e.g. book-to-market ratio) or negative (e.g. market value of equity).

16 The details are described in pg. 4398 of Green et al. (2017).

17 The excess market return is taken from Kenneth French’s data library.
(number of analysts covering stock), and sfe (scaled earnings forecast). On the other hand, some characteristics which are significant in their univariate regressions are not significant in multiple testing, although most have large t-statistics. This is the case of agr (asset growth, t-stat = -2.9), chatoia (industry-adjusted change in turnover, t-stat = 2.85), ear (earnings announcement return, t-stat = 2.93), egr (growth in common shareholder equity, t-stat = -2.84), grcapx (growth in capital expenditures, t-stat -2.70), grltlnoa (growth in long term net operating assets, -3.20), pchsalepchnvt (change in sales - change in inventory, t-stat = 1.58), and sue (unexpected quarterly earnings, t-stat = 2.57).

Table 2 reports statistics of the absolute pairwise correlations between the factors for the period during which all 83 factors (except the intercept) are available, a total of 114 months from July 2007 to December 2016. There are 3403 total pairwise correlations. The median absolute correlation is 0.179, and 90% of all absolute correlations are below 0.498. We also report the 10 largest absolute correlations. Some factors are highly correlated, and 4 correlations are higher than 0.90. Figure 1 plots the distribution of the absolute correlations. When these factors are used all together in the conventional regression equation, multi-collinearity problems would arise despite a weak cross-correlations between individual firm characteristics as in Green et al. (2017).

3.2. Test Assets

The Bayesian variable selection method is applied to thousands of common stocks listed on the New York Stock Exchange (NYSE), the American Stock Exchange (AMEX), and NASDAQ. We exclude financial stocks (Standard Industrial Classification code from 6000 to 6999) because their accounting practices and variables are not compatible with those of the other sectors. We also exclude a large number of microcap stocks whose market size is less than the bottom 20th percentile of market cap of NYSE stocks as well as penny stocks whose prices are less than US$1 at the beginning of test periods. When these stocks are included, our results would be affected too much by the market microstructure biases and thin trading by these stocks whose value is less than 3 percent of the total market.
value. For robustness purposes, we later investigate factor selection using micro-cap stocks only.

When considering individual stocks over long sample period, there is a serious survivorship bias. Therefore, we consider shorter sub-sample periods to minimize survivorship bias and also capture time variation in factor selection. When deciding the length of the sub-sample periods, we need to consider a trade-off between precision (using more data to conduct inference on factor selection) and the potential for survivorship bias. We also face a natural limit given the large number of candidate factors i.e. the number of months in each sub-sample period should be larger than that of factors.

Therefore, two different approaches have been used to balance these concerns. First, we divide our sample period into three sub-sample periods of 144 (January 1980 to December 1991), 144 (January 1992 to December 2003) and 156 (January 2004 to December 2016) months and apply the Bayesian variable selection method using all available factors in each sub-sample period\(^{18}\). This approach allows us to study a larger set of candidate factors, with some reduction in survivorship bias. The second approach consists of 5 shorter sub-sample periods, with the first 4 containing 90 months each, and the last containing 84 months. For these shorter sub-sample periods (not larger than 90 monthly observations), we restrict the number of candidate factors into 55 including the market excess return and the intercept. These are the factors that are significant in any of the regressions in Green et al. (2017).

To compare our results with those of previous studies and to assess the performance of our method, we also consider an extensive set of portfolios formed by sorting stocks according to different criteria\(^ {19}\). The portfolio return data are obtained from Kenneth French’s data library\(^ {20}\). We consider portfolios formed on univariate and bivariate sorts, as well as industry classification. The total number

\(^{18}\)These two break points are chosen considering the importance of research on firm characteristics (e.g., Fama & French (1992) and Jegadeesh & Titman (1993)) and the structural breaks in the performance of firm characteristics in cross-sectional asset returns (Green et al. (2017)).

\(^{19}\)Testing portfolios is motivated by the dependence we observe between the portfolio formation criteria and the selected factors. Lewellen, Nagel and Shanken (2007) argue that it is problematic to use portfolios formed on firm characteristics to test asset pricing models, because these portfolios will have a tight factor structure by construction. In this case, the idiosyncratic component of the model will be very small, and the factors will appear to be statistically significant cross-sectionally.

\(^{20}\)http://mba.tuck.dartmouth.edu/pages/faculty/ken.french/data_library.html
of portfolios considered is over 300\(^{21}\).

4. Selection of Asset Pricing Factors

We first discuss our main empirical findings for individual stocks, followed by the results of portfolios. These results have been obtained using an empirical Bayes prior for the factor sensitivities, i.e. we center each \( \beta_i \) around their OLS estimate by setting \( \beta_i \sim N((X'X)^{-1}X'r, c_i(X'X)^{-1}) \), with \( c_i = 1 \). We consider an equal prior probability for each factor: \( \pi_j = \pi = 0.5 \). The results for individual stocks are based on 10,000 iterations of the MCMC algorithm, while those for portfolios are based on 50,000 iterations. At the end of this section we test the robustness of our results with respect to these choices.

4.1. Individual Stocks as Test Assets

We apply our Bayesian variable selection methodology to individual stocks for various sub-sample periods using all available factors in the sub-sample periods in Section 3.2. These results are free from the biases inherent in using portfolios formed on characteristics which may be related to the factors we study, as discussed by Lo & Mackinlay (1990), Ferson et al. (1999), Berk (2000), Lewellen et al. (2010) and others.

4.1.1. Results using three sub-sample periods and the full set of factors

The results for the three sub-sample periods are reported in Table 3: January 1980 to December 1991, January 1992 to December 2003, and January 2004 to December 2016. The total number of non-microcap stocks in each period are 807, 893 and 967, respectively, while the number of candidate factors are 75, 81 and 83, respectively.

[Table 3 about here.]

For all sub-sample periods, models with less than 5 factors are generally selected by our Bayesian variable selection procedure. This is quite surprising, as

\(^{21}\)The univariate sort portfolios considered are those formed on size, book-to-market, operating profitability, investment, earnings-to-price, cashflow-to-price, dividend yield, momentum, short-term reversal, long-term reversal, beta, variance and residual variance. The bivariate sort portfolios include size and book-to-market, size and operating profitability, size and investing, book-to-market and operating profitability, book-to-market and investment, and operating profitability and investment. The industry portfolios comprise 49 industries.
the number of possible models is enormous, varying from $2^{75}$ in the first sub-sample period to $2^{81}$ in the last sub-sample period. However, we do not find that a single model (a set of factors) or factors (other than the market factor) are consistently selected across sub-sample periods. Additionally, among the large number of candidate factors, only 13 factors are ever selected over the three sub-sample periods. These factors are mkt (the market return), aeavol (abnormal earnings announcement volume), chmom (change in 6-month momentum), chanalyst (change in number of analysts covering stock), ear (earnings announcement return), ep (earnings-to-price), herf (industry sales concentration), mom1m (1-month momentum), ms (Mohanram (2005a)'s financial statement score), pctacc (percent accruals), saleinv (sales to inventory), tb (tax income to book income), and intercept. When factors whose marginal posterior probabilities are above 0.5 are counted in any of the sub-sample period, we have only four factors, i.e., mkt, chmom, herf, and mom1m.

During the first sub-sample period, from January 1980 to December 1991, there is a substantial amount of model uncertainty, as the posterior probability of the best model is quite low. The best model includes the market factor and chmom (change in 6-month momentum), with a posterior probability of 0.24. Other models include either mom1m (1-month momentum) and/or ms (Mohanram (2005a)'s financial statement score). Lower probability models include other factors formed on ep (earnings-to-price) or tb (tax income to book income). The only factors that have marginal posterior probabilities higher than 0.5 (our prior) during this period are the market factor and chmom (change in 6-month momentum).

In the second sub-sample period, which comprises the period from January 1992 to December 2003, model uncertainty is much lower, with the best model including only the market factor with a high posterior probability of 0.64. The second best model includes aeavol (abnormal earnings announcement volume) or pctacc (percent accruals), the latter with very low posterior probability.

Finally, in the last sub-sample period, from January 2004 to December 2016, two models appear with similar posterior probabilities. The best model, with posterior probability 0.24, includes the intercept and 3 factors. In addition to the market return, this model includes herf (industry sales concentration) and mom1m (1-month momentum). The second best model, with posterior probability 0.20, drops the intercept and includes chanalyst (change in number of analysts covering stock). We note that many models include the intercept, which we interpret as evidence that these models do not explain the individual stock returns well during this period.

These results suggest some interesting points. First, factor selection varies
quite a lot through time, with no specific model dominating the others. The only factor for which appears consistently across all sub-sample periods is the excess market return. The other factor that appears in more than one sub-sample period is mom1m (1-month momentum), which is included in the best models in the first and last sub-sample periods. All other factors matter only during one sub-sample period. Second, the high posterior probability models do not include the popular factors (other than the market return) that have been proposed in the literature, e.g., FF3, FF5, CZ or HXZ. The additional factors that are selected by our Bayesian variable selection method are related to other anomalies or characteristics such as short-term reversal, momentum, earnings announcement volume, change in the number of analysts covering stocks, and industry concentration. Third, the total number of factors selected in these models over all sub-sample periods is small relative to the total number of candidate factors. Only 13 factors (out of more than 80) are ever selected by the variable selection methodology, and from these, only 4 factors have marginal posterior probabilities higher than 0.5 in any of the sub-sample periods.

4.1.2. Results using five sub-sample periods and the reduced set of factors

The selection of the intercept during the last sub-sample period suggests that the 13 models (8 factors) do not fully explain individual stock returns. Moreover, the large numbers of models in the first and third sub-sample periods indicate model uncertainty during these periods. In this subsection we explore the possibility that these results arise because of the relatively long sub-sample periods, i.e., 12 years. When the true model is time-varying, a linear regression model over a long period requires a larger number of factors or even does not explain asset returns (Jagannathan and Wang, 1996).

Five shorter sub-sample periods are used to test individual stocks: January 1980 to June 1987, July 1987 to December 1994, January 1995 to June 2002, July 2002 to December 2009, and January 2010 to December 2016. The number of stocks varies from 1,014 in the first sub-sample period to 1,225 in the last sub-sample period. By selecting factors that are significant in any of the regressions in Green et al. (2017), the numbers of factors we test for these five sub-sample periods range from 44 to 49. The results are reported in Table 4.

[Table 4 about here.]

The results show similarities with those of 3 longer sub-sample periods and the full set of candidate factors in Table 3. No single model or factor (other than
the market factor) is consistently selected across sub-sample periods except for the excess market return. However, a few important differences from the shorter sub-sample periods can be summarized as follows. First, model uncertainty decreases with test period. At most 4 factors are selected rather than 7 factors in 3, and only 10 factors (out of almost 50) are selected by the variable selection methodology. These are: mkt (market excess return), aeavol (abnormal earnings announcement volume), bm (book-to-market), chmom (change in 6-month momentum), ear (earnings announcement return), mom1m (1-month momentum), mve_ia (industry adjusted size), pchsle.pchrect (change in sales - change in A/R), pctacc (percent accruals), and sue (unexpected quarterly earnings). From these, only 6 have marginal posterior probabilities higher than 0.5 (mkt, chmom, ear, mom1m, mve_ia, and sue). Second, despite the smaller numbers of factors, the intercept is not selected in any of the sub-sample periods, which can be interpreted that these 10 factors are enough to explain individual stocks. These results suggest that the possibility of model mis-specification decreases when sample period becomes shorter.

Starting in Panel A, a single model is selected during the first sub-sample period; the model includes the mkt (market excess return) and chmom (change in 6-month momentum) factors. Panel B shows that, during the period from July 1987 to December 1994, ear (earnings announcement return) and mom1m (1-month momentum) factors need to be added on top of these two factors. Model uncertainty is still very low, with only two models having relevant posterior probabilities. The next three sub-sample periods show higher model uncertainty, and different factors are included in the best models. In the period from January 1995 to June 2002 (Panel C), the best model includes only the market return, with a posterior probability of 0.44. The next best models require either pctacc (percent accruals), mom1m (1-month momentum), or aeavol (abnormal earnings announcement volume), although with much lower posterior probabilities. During the period from July 2002 to December 2009 (Panel D), the best model includes the market return and sue (unexpected quarterly earnings), with a posterior probability of 0.44. The next best models include bm (book-to-market) or pchsle.pchrect (change in sales - change in A/R) with lower posterior probabilities. Finally, in the last period, from January 2010 to December 2016, we see more model uncertainty regarding the best model, as the posterior probabilities of the three best models are quite similar (0.36, 0.28, and 0.24). The best models include, in addition to the market return, mom1m (1-month momentum), mve_ia (industry-adjusted market value of equity), sue (unexpected quarterly earnings) or a combination thereof.

The only factor for which we find consistent evidence for all sub-sample pe-
riods is the excess market return. Other factors which are selected in some sub-sample periods, such as chmom (change in 6-month momentum), sue (unexpected quarterly earnings) and mom1m (1-month momentum), are not those in models such as FF5 and HXZ. Exceptions are the inclusion of bm (book-to-market) in Panel D (although with low posterior probability) and a size factor (mve ie) in Panel E. The additional factors that are selected to explain individual stocks are related to other anomalies such as short-term reversal, earnings announcement returns, surprise earnings etc.

4.1.3. Which factors explain the returns on microcap stocks?

The main results with non-microcap stocks may be different from those with microcap stocks. Many previous studies report that microcap stocks perform differently mainly due to their illiquidity (Baker & Wurgler, 2006; Stambaugh et al., 2012; Antoniou et al., 2015). Therefore, in this subsection, we apply our methodology to the set of microcap stocks only in each sub-sample period, to investigate which factors matter to explain their returns.

[Table 5 about here.]

The results are reported in Table 5. There are similarities in the selected factors over different sub-sample periods with respect to those of non-microcap stocks in Table 4. For example, chmom (change in 6-month momentum) is selected for both groups of stocks during the first sub-sample period and ear (earnings announcement return) is selected in the second sub-sample period. One interesting result is that, during the period January 1995 to June 2002 (Panel C), the two highest posterior probability models do not include the market return factor. The two best models, with together represent a posterior probability of 0.88, include aeavol (abnormal earnings announcement volume) and chanalyst (change in number of analysts covering stock). A possible explanation is that the microcap universe during the period of the high-tech bubble of the 1990s includes a high number of small technology stocks whose prices were extremely sensitive to these variables during this unusual period, and not very sensitive to overall market movements, as many investors were captivated by the possibility of finding the next “hot” technology stock (during the build-up of the bubble) or concerned about any news regarding their technology stocks during the bursting of the bubble.

---

22We report results for five sub-sample periods and the reduced set of factors. The results with three sub-sample periods and the full set of factors do not differ significantly and are available upon request.
Interestingly, smaller numbers of factors are selected compared to non-microcap stocks, and these factors are not the popular ones. Overall, only 6 factors are ever selected in any of the periods: mkt (market excess return), aeavol (abnormal earnings announcement volume), chmom (change in 6-month momentum), ear (earnings announcement return), pchsapechrect (change in sales - change in A/R) and sue (unexpected quarterly earnings). From these, only 3 have a marginal posterior probability higher than 0.5: mkt, aeavol, and ear.

4.2. Portfolios as Test Assets

For portfolios of stocks, we test the whole sample period from 1980 to 2016 because there is no survivorship bias in this case. The best model for each set of portfolios and the associated posterior probabilities are reported in Table 6. Several interesting results are reported as follows.

First, when portfolios are formed on firm characteristics, factors related to these characteristics are typically included in the best models. For example, the best model to explain portfolios formed on size includes mve_ia (industry-adjusted size); for portfolios formed on book-to-market, the bm factor is included; for portfolios formed on operating profitability, roic (return on invested capital), which is highly correlated with the factor formed on roe (return on equity), is included, and so on. This pattern also holds for portfolios formed on bivariate sorts. For example, the 25 Fama-French portfolios formed on size and book-to-market require a size factor (mve_ia) and lev (leverage, which has almost 0.70 correlation with the bm factor).

The pattern of dependence between the variable used for portfolio formation and the selected factors reflects the concerns expressed by Lo & Mackinlay (1990), Ferson et al. (1999), Berk (2000), Roll (1977) and Lewellen et al. (2010). The selected models appear to be incorrectly promising because none of the high posterior probability models include the intercept even for the long testing period, i.e., 444 monthly data.

Second, model uncertainty increases for the portfolios and varies significantly across the different sets of factors. The posterior probabilities of the best models varies from 0.10 for the portfolios formed on long-term reversal to 0.57 for the portfolios formed on operating profitability. For the double sorted portfolios, the posterior probabilities of the best models are around 0.2. Even for the portfolios formed on characteristics related to widely used factor models, the best models also include factors other than the firm characteristics that are used to form portfolios, for example, Fama & French (2015), Hou et al. (2015b), and others.
The model uncertainty indicates that sorting stocks to one or two firm characteristics does not completely remove the effects of other firm characteristics. If firm characteristics are not correlated, then portfolios formed on one firm characteristic should not be explained by factors formed on other firm characteristics. The model uncertainty confirms the problems raised by Fama and French (2008) that forming portfolios based on one or more firm characteristics does not guarantee that these portfolios are not affected by other firm characteristics.

Third, once again, the one most important factor is invariably the market factor. In untabulated results, we calculate the average posterior probability of all factors across all sets of portfolios, and find that the only factor with an average posterior probability higher than 0.5 is the excess market return, which is consistent with the results we obtained using individual stocks.

Finally, we find that the results for the 49 industry portfolios support a five-factor model with the market factor, beta, illiquidity, leverage and organizational capital. Organizational capital represents Selling, general and administrative expenses which is a distinct factor that can only be found in the sector portfolios23.

4.3. Robustness of Results

We investigate how sensitive our results are with respect to the informativeness of priors. We perform robustness test by changing the value of $c$, a scaling parameter related to the prior variance of the regression coefficient vector $\beta$. Instead of $c = 1$ that we used for our main results, we use $c = 5$, a much less informative prior. We perform the calculations for non-microcap and microcap stocks using the five sub-sample periods, and for each set of portfolios using the whole sample.

The results with less informative priors ($c = 5$) are almost identical to those with $c = 1$ in terms of factor selection and model probabilities. For non-microcap stocks with $c = 5$, the results are not different from those we report in Table 4, and thus we do not report them. For microcap stocks, the results of which are reported in Table 7, there is slight difference in the posterior probability of the market factor, but the difference is only marginal.

---

Table 8 reports the best models and associated posterior probabilities for the different sets of portfolios when the procedure is run with $c = 5$. In most cases, the best model includes fewer factors compared to the results obtained with $c = 1$, which is expected as the prior is less informative, and it becomes a priori less likely that factor sensitivities would be generated in regions where the associated $\gamma_j$ is high, as discussed for example in O’Hara & Sillanpää (2009). Model uncertainty is smaller, in the sense that the best models have higher posterior probabilities, which reflects the fact that, as the priors of the regression coefficients become more diffuse, fewer factors are selected, increasing model probabilities. In a few cases, some factors are dropped and others are included, but similar patterns we reported previously still hold, i.e. factors related to the characteristics used for portfolio formation remain in the model.

Overall, we conclude that our results are not sensitive to the prior specification, particularly for individual stocks, where we find virtually identical results.

4.4. Comparison with Other Studies

Although there have been several studies that apply a Bayesian approach to asset pricing, comparison is challenging due to the differences in data, both in terms of factors as well as test assets. Specifically, compared to previous studies that use a Bayesian variable selection procedure to identify asset pricing factors (Ericsson & Karlsson (2003), Ouysse & Kohn (2010), Puelz et al. (2017)), the most important difference is that we also apply our method to thousands of individual stocks, while these studies only use portfolios. Another relevant difference is that Ericsson & Karlsson (2003) and Ouysse & Kohn (2010) include macroeconomic factors, while we chose to focus on tradable factors based on cross-sectional patterns reported in the literature. Our set of candidate factors is also much broader.

Our tests using a large collection of sets of portfolios revealed a strong pattern of dependence between the portfolio formation criteria and the selected factors, suggesting skepticism in interpreting results of studies that apply these techniques using portfolios which are related to the candidate factors. Our results using a set of 49 industry portfolios (which are not directly formed based on sorting accounting or return characteristics) suggest a model which includes, in addition to the market factor, factors related to beta, illiquidity, leverage, and organizational capital. In comparison, e.g. Ericsson & Karlsson (2003)’s results using 10 industry portfolios support the Carhart model with the addition of macroeconomic factors (credit risk spread and industrial production). For portfolios formed on size and
book-to-market ratio, our results are comparable to Puelz et al. (2017) and Ericsson & Karlsson (2003), but not surprisingly they favor model which include factors (co)related to size and book-to-market, with the addition of illiquidity in our case.

Recently, Barillas & Shanken (2017) developed a Bayesian asset pricing test which can be calculated in closed form and, in principle, be used to test all possible models using a set of candidate factors. However, in their empirical tests they only considered the factors in FF5, HXZ, as well as a different version of HML proposed by Asness & Frazzini (2013) and momentum (a total of 10 factors). Their tests, conducted on the factors themselves and on sets of portfolios formed on either size and momentum or book-to-market and investment, support a six-factor model with the market return, the HXZ versions of investment (IA) and profitability (ROE), the FF5 version of size (SMB), the modified HML factor from Asness & Frazzini (2013), and the momentum factor. These results are not unexpected, as the portfolios are related to the factors.

Since we build tradable factors based on the characteristics studied by Green et al. (2017), it is interesting to compare our results with theirs. They identify 9 characteristics which are significant determinants of non-microcap stocks. In comparison with our results, the only commonalities are earnings announcement return and 1-month momentum, while we also find that change in 6-month momentum, market value of equity, and unexpected quarterly earnings are important factors, for some periods. When they include microcaps, 3 additional characteristics (book-to-market, change in 6-month momentum, and zero trading days) are also significant. There are similarities with our results, as we find that change in the number of analysts, earnings announcement, and change in 6-month momentum are important factors to explain microcap stocks. However, our results suggest that these factors are not consistently selected in different sub-sample periods. Also, similarly to Green et al. (2017), we find that the factors from prominent models such as FF and HXZ are not relevant to explain individual stocks.

Our work is also related to recent studies that test factors using procedures to directly account for data mining issues. For example, using a multiple testing framework based on a bootstrapping procedure with individual stocks, Harvey & Liu (2016) test a set of 14 factors that includes many of the ones in our study.

\[24\] These are cash, change in the number of analysts, earnings announcement return, one-month momentum, the number of consecutive quarters with an increase in earnings over the same quarter a year ago, annual R&D to market cap, return volatility, share turnover, and volatility of share turnover.
and find evidence that the most important factor is, by far, the market return, with only a small role for the profitability factor. We note that, while Harvey & Liu (2016)’s approach and set of factors is quite different from ours, their conclusion regarding the importance of the market return for individual stocks is mirrored in our results.

5. Conclusion

The asset pricing literature has proposed hundreds of factors to explain asset returns, most within the last two decades. It is unlikely that so many factors matter to determine security prices; rather, some are likely to be redundant, while others (or even most) may be product of data mining. In this paper we propose a Bayesian variable selection methodology to explore the most promising linear factor models, given a set of candidate factors and a set of assets. The proposed methodology builds on the literature on Bayesian variable selection in multivariate regression models and provides a computationally feasible means of exploring model selection in large panels of data.

We apply the methodology to identify the most relevant factors to explain returns on individual stocks, as well as an extensive set of portfolios. We consider a large set of 83 candidate factors, including 82 tradable factors based on various firm characteristics identified in the literature, as well as the market return suggested by Sharpe (1964).

Using individual stocks, we find that (i) the only factor that matters across all sub-sample periods is the market excess return; (ii) factor selection varies substantially over time, with no specific model dominating the others in the various sub-sample periods we investigate; (iii) other factors (in addition to the market return) which are selected for specific sub-sample periods are not the factors in widely used models such as the ones proposed by Fama & French (1992, 1996), Chen & Zhang (2010), Hou et al. (2015b) and Fama & French (2015). The additional factors that are selected in certain periods to explain individual stocks are related to other anomalies or characteristics such as short-term reversal, change in 6-month momentum, earnings announcement return, change in the number of analysts covering stocks, industry concentration, unexpected quarterly earnings, and industry-adjusted size; (iv) the total number of factors selected in these models over all sub-sample periods is small relative to the total number of candidate factors, i.e. only 10 factors (out of more than 80) are ever selected by the variable selection methodology, and from these, only 5 to 6 have a marginal posterior probability higher than 0.5; and (v) the factors that matter to explain microcap stocks
include factors formed on change in six-month momentum, abnormal earnings announcement volume and change in number of analysts covering stock.

Our work builds on the literature on asset pricing factor selection, by showing that, despite the large number of factors that have been proposed, only a handful appear to explain the returns on individual stocks, with the market return remaining the most important factor. We leave for future research refinements of the model to allow even more efficient exploration of the model space when the numbers of factors and assets are large.

Figure 1: **Histogram of absolute pairwise factor correlations**

The figure plots the distribution of the pairwise absolute correlations of 83 factors, including 82 factors formed on firm characteristics obtained following Green *et al.* (2017), and the market excess return.
The 82 factors are constructed from value-weighted portfolios sorting all non-microcap stocks into deciles based on the characteristics of Green et al. (2017). The factor returns are calculated as the difference between the top and bottom deciles. We also report statistics for the market excess return, calculated as the excess return on the market, value-weight return of all CRSP firms incorporated in the US and listed on the NYSE, AMEX, or NASDAQ that have a CRSP share code of 10 or 11 at the beginning of month t, minus the one-month Treasury bill rate. The table reports the first date at which the factor has been calculated, the total number of months, the average monthly return, the standard deviation, and the t-statistic. An *bold line denotes a Dependent False Discovery Rate (DFDR) p-value lower than 0.05, calculated using the method of Benjamini & Yekutieli (2001).

Table 7: Robustness test - posterior model probabilities obtained with microcap stocks, $c = 5$

We apply the Bayesian variable selection method to all microcap stocks in each sub-sample period and report the models with the highest posterior probability. The set of candidate factors includes all significant factors in Green et al. (2017) as well as the excess market return. We report results for $c = 5$, where $c$ is a scaling parameter related to the prior variance of the regression coefficient vector $\beta$.

We apply the Bayesian variable selection methodology to sets of portfolios formed according to various criteria, using factors for which data is available for the period 1980 to 2016. The table reports the best model, i.e. the model with highest posterior probability, the number of factors in the model, and the posterior probability. We report results for $c = 5$, where $c$ is a scaling parameter related to the prior variance of the regression coefficient vector $\beta$.

Appendix A. Bayesian Estimation of the SUR Model

This section details the estimation of SUR model using the Gibbs sampler. The SUR model with common regressors can be written as

\[ \mathbf{r}_i = \mathbf{X}\beta_i + \mathbf{e}_i, \quad i = 1, \ldots, N \]  

(A.1)

where, for each equation \( i = 1, \ldots, N \), \( \mathbf{r}_i \) is the \( T \times 1 \) vector of observed responses, \( \mathbf{X} \) is the matrix of regressors with dimension \( T \times K \), \( \beta_i = (\beta_{i,1}, \ldots, \beta_{i,K})' \) is a \( K \times 1 \) vector of unknown regression coefficients and \( \mathbf{e}_i \) is a \( T \times 1 \) vector of disturbances. The system can be stacked in a single equation

\[
\begin{bmatrix}
\mathbf{r}_1 \\
\mathbf{r}_2 \\
\vdots \\
\mathbf{r}_N 
\end{bmatrix} =
\begin{bmatrix}
\mathbf{X} & 0 & \cdots & 0 \\
0 & \mathbf{X} & \cdots & 0 \\
\vdots & \vdots & \ddots & \vdots \\
0 & 0 & \cdots & \mathbf{X}
\end{bmatrix}
\begin{bmatrix}
\beta_1 \\
\beta_2 \\
\vdots \\
\beta_N
\end{bmatrix}
+ 
\begin{bmatrix}
\mathbf{e}_1 \\
\mathbf{e}_2 \\
\vdots \\
\mathbf{e}_N
\end{bmatrix}
\]  

(A.2)

Letting \( \hat{\mathbf{e}} = (\mathbf{e}_1', \mathbf{e}_2', \ldots, \mathbf{e}_N')' \), the basic assumption of the SUR model is \( \mathbb{E}(\hat{\mathbf{e}}\hat{\mathbf{e}}') = \mathbf{\Sigma} = \mathbf{\Sigma} \otimes \mathbf{I}_T \). We assume \( \hat{\mathbf{e}} \sim N(0, \mathbf{\Sigma} \otimes \mathbf{I}_T) \) and the following prior distributions for \( \hat{\beta} \) and \( \mathbf{\Sigma} \):

\[
\hat{\beta} \sim N(\mathbf{b}_0, \mathbf{B}_0) \\
\mathbf{\Sigma} \sim IW(\gamma_0, \Phi_0).
\]  

(A.3)

The likelihood for the full system of equations is given by

\[
L(\hat{\beta}, \mathbf{\Sigma}|\mathbf{X}, \mathbf{r}) = (2\pi)^{-\frac{NT}{2}} |\mathbf{\Sigma}|^{-\frac{T}{2}} \exp \left( -\frac{1}{2} (\mathbf{r} - \mathbf{X}\hat{\beta})'(\mathbf{\Sigma}^{-1})(\mathbf{r} - \mathbf{X}\hat{\beta}) \right).
\]  

(A.4)

Let \( \mathbf{\Sigma}^{-1} = \mathbf{P}'\mathbf{P} \) and define \( \tilde{\mathbf{X}} = \mathbf{P}\mathbf{X} \), \( \tilde{\mathbf{r}} = \mathbf{P}\mathbf{r} \). Then \( \tilde{\mathbf{X}}'\mathbf{\Sigma}^{-1}\tilde{\mathbf{X}} = \tilde{\mathbf{X}}'\tilde{\mathbf{X}} \) and \( \tilde{\mathbf{X}}'\mathbf{\Sigma}^{-1}\tilde{\mathbf{r}} = \tilde{\mathbf{X}}'\tilde{\mathbf{r}} \) and we can write

\[
L(\hat{\beta}, \mathbf{\Sigma}|\mathbf{X}, \mathbf{r}) \propto \exp \left( -\frac{1}{2} (\tilde{\mathbf{r}} - \tilde{\mathbf{X}}\hat{\beta})'(\mathbf{\Sigma}^{-1})^{-1}(\tilde{\mathbf{r}} - \tilde{\mathbf{X}}\hat{\beta}) \right).
\]  

(A.5)

Appendix A.1. Distribution of \( \hat{\beta}|\mathbf{\Sigma}, \tilde{\mathbf{r}} \)

We will use the notation \( f(\cdot) \) to denote a generic probability density function, and \( f(\cdot|\cdot) \) to denote a conditional density. The prior for \( \hat{\beta} \) is given by

\[
f(\hat{\beta}|\mathbf{\Sigma}) \propto \exp \left( -\frac{1}{2}(\hat{\beta} - \mathbf{b}_0)'\mathbf{B}_0^{-1}(\hat{\beta} - \mathbf{b}_0) \right).
\]  

(A.6)
where $b_0, B_0$ are known. Therefore the posterior conditional distribution of $\tilde{\beta}|\Omega, \tilde{r}$ is

$$f(\tilde{\beta}|\Omega, r) \propto f(\tilde{\beta}|\Omega)L(\tilde{\beta}, \Sigma|X, \tilde{r})$$

$$\propto \exp\left(-\frac{1}{2} (\tilde{\beta} - b_0)' B_0^{-1} (\tilde{\beta} - b_0) \right) \exp\left(-\frac{1}{2} (\tilde{r}' - \tilde{X}' \tilde{\beta})'(\tilde{r} - \tilde{X}' \tilde{\beta}) \right).$$

Expanding the products and collecting terms on $\tilde{\beta}$, we have

$$f(\tilde{\beta}|\Omega, r) \propto \exp\left(-\frac{1}{2} \left[\tilde{\beta}'(B_0^{-1} + \tilde{X}'\tilde{X}) \tilde{\beta} - 2\tilde{\beta}'(B_0^{-1} b_0 + \tilde{X}' \tilde{r}) \right] \right).$$

Letting $B_1 = (B_0^{-1} + \tilde{X}'\tilde{X})^{-1}$ we obtain

$$f(\tilde{\beta}|\Omega, r) \propto \exp\left(-\frac{1}{2} \left[\tilde{\beta}' B_1^{-1} \tilde{\beta} - 2\tilde{\beta}' (B_0^{-1} b_0 + \tilde{X}' \tilde{r}) \right] \right).$$

Finally, completing the quadratic form and letting

$$b_1 = (B_0^{-1} + \tilde{X}'\tilde{X})^{-1} (B_0 b_0 + \tilde{X}' \tilde{r}),$$

we obtain

$$f(\tilde{\beta}|\Omega, r) \propto \exp\left(-\frac{1}{2} \left[ (\tilde{\beta} - b_1)' B_1^{-1} (\tilde{\beta} - b_1) \right] \right),$$

therefore recognizing that $\tilde{\beta}|\Omega, r \sim N(b_1, B_1)$.

**Appendix A.2. Sequential generation of $\beta_i|\tilde{\beta}_{-i}, \Sigma, \tilde{r}$**

Recall that $\tilde{X}$ has dimension $NT \times NK$ and $\Omega$ has dimension $NT \times NT$. Therefore, for large panels (when $N$ is large), the expressions above will require multiplication and inversion of large matrices. An alternative and quicker approach for large panels consists of sampling each $\beta_i$ conditionally on the remaining $\beta_j, j \neq i$ and $\Sigma$. Let $\tilde{\beta}_{-i}$ denote the full vector $\tilde{\beta}$ with the entries corresponding to $i$ removed. Assume that

$$\beta_i|\tilde{\beta}_{-i}, \Sigma \sim N(b_{0,i}, B_{0,i}), \quad i = 1, \ldots, N.$$

For simplicity, let’s assume that $i = 1$, that is, we are interested in generating $\beta_1|\tilde{\beta}_{-1}, \Sigma$. Partition the SUR system as follows:

$$\tilde{r} = \begin{bmatrix} r_1 \\ r_{-1} \end{bmatrix}, \tilde{\beta} = \begin{bmatrix} \tilde{\beta}_1 \\ \tilde{\beta}_{-1} \end{bmatrix}, \tilde{X} = \begin{bmatrix} X & 0 \\ 0 & \tilde{X}_{-1} \end{bmatrix},$$

$$\begin{bmatrix} B_0 & 0 \\ 0 & B_{-1} \end{bmatrix}.$$
where $\tilde{X}_{-1}$ collects the structure of $\tilde{X}$ for the remaining $N - 1$ equations. Then we can write

$$
\tilde{r} - X\tilde{\beta} = \begin{bmatrix}
    r_1 \\
    \vdots \\
    r_{-1}
\end{bmatrix} - \begin{bmatrix}
    X & 0 \\
    0 & \tilde{X}_{-1}
\end{bmatrix} \begin{bmatrix}
    \tilde{\beta}_1 \\
    \tilde{\beta}_{-1}
\end{bmatrix}
= \begin{bmatrix}
    \tilde{r}_1 - X\tilde{\beta}_1 \\
    \tilde{r}_{-1} - \tilde{X}_{-1}\tilde{\beta}_{-1}
\end{bmatrix}
$$

(A.7)

Recall that $\Omega^{-1} = \Sigma^{-1} \otimes I_T$ and let $(\Sigma^{-1})_{i,j} = \sigma^{ij}$ denote element $(i, j)$ of $\Sigma^{-1}$. The corresponding partition of $\Omega^{-1}$ is

$$
\Omega^{-1} = \begin{bmatrix}
    \sigma^{11}I & \sigma^{12}I & \cdots & \sigma^{1N}I \\
    \sigma^{21}I & \sigma^{22}I & \cdots & \sigma^{2N}I \\
    \vdots & \vdots & \ddots & \vdots \\
    \sigma^{N1}I & \sigma^{N2}I & \cdots & \sigma^{NN}I
\end{bmatrix} = \begin{bmatrix}
    \sigma^{11}I & A \\
    A' & \Omega_{-1}
\end{bmatrix}.
$$

(A.8)

In the partition of $\Omega^{-1}$ above, we note that $\sigma^{11}I$ has dimension $T \times T$, $A$ has dimension $T \times (N - 1)T$, and $\Omega_{-1}$ has dimension $(N - 1)T \times (N - 1)T$. Using A.7 and A.8 we can now write the weighted sum of residuals as follows.

$$(\tilde{r} - \tilde{X}\tilde{\beta})'\Omega^{-1}(\tilde{r} - \tilde{X}\tilde{\beta}) =$$

$$
\begin{bmatrix}
    (r_1 - X\beta_1)' \\
    (\tilde{r}_{-1} - \tilde{X}_{-1}\tilde{\beta}_{-1})'
\end{bmatrix} \begin{bmatrix}
    \sigma^{11}I & A \\
    A' & \Omega_{-1}
\end{bmatrix} \begin{bmatrix}
    r_1 - X\beta_1 \\
    \tilde{r}_{-1} - \tilde{X}_{-1}\tilde{\beta}_{-1}
\end{bmatrix}
$$

Expanding the right-hand side and collecting terms, we obtain

$$(\tilde{r} - \tilde{X}\tilde{\beta})'\Omega^{-1}(\tilde{r} - \tilde{X}\tilde{\beta}) =$$

$$
\sigma^{11}(r_1 - X\beta_1)'(r_1 - X\beta_1) + 2(r_1 - X\beta_1)'A(\tilde{r}_{-1} - \tilde{X}_{-1}\tilde{\beta}_{-1}) + (\tilde{r}_{-1} - \tilde{X}_{-1}\tilde{\beta}_{-1})'\Omega_{-1}(r_1 - X\beta_1)$$

(A.9)

Now the posterior of $\beta_1|\tilde{\beta}_{-1}, \Sigma, \tilde{r}$ can be calculated as
and completing the squares, we obtain
\[ f(\beta_1 | \tilde{\beta}_{-1}, \Sigma, \tilde{r}) \propto \exp \left( -\frac{1}{2} (\beta_1 - b_{0,1})'B_{0,1}^{-1}(\beta_1 - b_{0,1}) \right) \]
\[ \times \exp \left( -\frac{1}{2}(\tilde{r} - \tilde{X}\tilde{\beta})'\Omega^{-1}(\tilde{r} - \tilde{X}\tilde{\beta}) \right) \]
\[ \propto \exp \left( -\frac{1}{2} \left[ (\beta_1 - b_{0,1})'B_{0,1}^{-1}(\beta_1 - b_{0,1}) \right. \right. \]
\[ + \sigma^{11}(r_1 - X\tilde{\beta}_1)'(r_1 - X\tilde{\beta}_1) + 2(r_1 - X\tilde{\beta}_1)'A(\tilde{r}_{-1} - \tilde{X}_{-1}\tilde{\beta}_{-1}) \]
\[ \left. \left. + (\tilde{r}_{-1} - \tilde{X}_{-1}\tilde{\beta}_{-1})'\Omega_{-1}^{-1}(r_1 - X\beta_1) \right] \right). \]

where we have substituted (A.9). Expanding the expression above and removing terms that are constant or do not depend on $\beta_1$ yields:
\[ f(\beta_1 | \tilde{\beta}_{-1}, \Sigma, \tilde{r}) \propto \exp \left( -\frac{1}{2} \left[ \beta_1'B_1^{-1}_1\beta_1 - 2\beta_1'B_0^{-1}_1b_{0,1} + \sigma^{11}(1X'X\beta_1 \right. \right. \]
\[ - 2r_1'X\beta_1) - 2\beta_1'X'A(\tilde{r}_{-1} - \tilde{X}_{-1}\tilde{\beta}_{-1}) \right) \left. \right) \]
\[ \propto \exp \left( -\frac{1}{2} \left[ \beta_1'(B_0^{-1}_1 + \sigma^{11}X'X)\beta_1 \right. \right. \]
\[ - 2\beta_1'(B_0^{-1}_1b_{0,1} + \sigma^{11}X'(r_1 - (\sigma^{11})^{-1}A(\tilde{r}_{-1} - \tilde{X}_{-1}\tilde{\beta}_{-1})) \left. \right) \right) \]

Now letting:
\[ \begin{align*}
    r_i^* &= r_i - (\sigma^{ii})^{-1}A(\tilde{r}_{-i} - \tilde{X}_{-i}\tilde{\beta}_{-i}) \\
    B_{1,i} &= (B_{0,1}^{-1} + \sigma^{ii}X'X)^{-1} \\
    b_{1,i} &= (B_{0,1}^{-1} + \sigma^{ii}X'X)^{-1}(B_{0,1}^{-1}b_{0,1} + \sigma^{ii}X'r_i^*)
\end{align*} \]

and completing the squares, we obtain
\[ f(\beta_1 | \tilde{\beta}_{-1}, \Sigma, \tilde{r}) \propto \exp \left( -\frac{1}{2} (\beta_1 - b_{1,i})'B_{1,i}^{-1}(\beta_1 - b_{1,i}) \right), \]

therefore establishing $\beta_1 | \tilde{\beta}_{-1}, \Sigma, \tilde{r} \sim N(b_{1,i}, B_{1,i})$. More generally, we could have placed any of the equations in the first position in our partition, so it follows that $\beta_{1 | \tilde{\beta}_{-i}, \Sigma, \tilde{r} \sim N(b_{1,i}, B_{1,i})$, with
\[ \begin{align*}
    r_i^* &= r_i - (\sigma^{ii})^{-1}A(\tilde{r}_{-i} - \tilde{X}_{-i}\tilde{\beta}_{-i}) \\
    B_{1,i} &= (B_{0,i}^{-1} + \sigma^{ii}X'X)^{-1} \\
    b_{1,i} &= (B_{0,i}^{-1} + \sigma^{ii}X'X)^{-1}(B_{0,i}^{-1}b_{0,i} + \sigma^{ii}X'r_i^*)
\end{align*} \]
where $A$ now is defined appropriately to contain the terms for $j \neq i$.

Note that $r^*_i$ is the vector of responses for equation $i$, subtracted from a weighted average of the residuals from the remaining $N - 1$ equations, where the weights depend on the elements of $\Sigma^{-1}$. Thus, the posterior variance of $\beta_1|\tilde{\beta}, \tilde{r}$ depends on the covariance of the residuals of the equations. If these are zero, that is, if the system is composed of actually unrelated regressions, then $r^*_i = r_i$ and the posterior covariance matrix reduces to the one that would be obtained for the single regression equation $i$, as one would expect.

**Appendix A.3. Distribution of $\Sigma|\tilde{\beta}, \tilde{r}$**

Since $\Omega = \Sigma \otimes I_T$, it suffices to derive the conditional distribution of $\Sigma|\tilde{\beta}, \tilde{r}$. The prior for $\Sigma$ is an inverted Wishart distribution with parameters $\nu_0$ and $\Phi_0$:

$$f(\Sigma) \propto |\Sigma|^{-\nu_0/2} \exp \left( -\frac{1}{2} \text{Tr} \left( \Phi_0 \Sigma^{-1} \right) \right).$$

To derive the posterior of $\Sigma|\tilde{\beta}, \tilde{r}$, it is convenient to write the likelihood function in a different way, by arranging the system such that, instead of stacking all $T$ observations for each equation, we will stack the $N$ equations for each observation. For an arbitrary observation $t$, let $r_t = (y_{t,1}, y_{t,2}, \ldots, y_{t,N})'$ denote the $N \times 1$ vector of observed responses, $x_t = (x_{t,1}, x_{t,2}, \ldots, x_{t,K})'$ denote the $K \times 1$ vector of predictors, and $e_t = (e_{t,1}, e_{t,2}, \ldots, e_{t,N})'$ denote the vector of error terms. Then we can write

$$r'_t = x'_t \begin{bmatrix} \beta_1 & \beta_2 & \cdots & \beta_N \end{bmatrix} + e'_t, \quad t = 1, \ldots, T. \quad \text{(A.10)}$$

The SUR correlation structure now can be represented conveniently as $\mathbb{E}(e_te'_t) = \Sigma$. The likelihood at each observation is $L_t = (2\pi)^{-\frac{N}{2}} |\Sigma|^{-\frac{T}{2}} \exp \left( -\frac{1}{2} e'_t \Sigma^{-1} e_t \right)$ and the full likelihood can be written as

$$L = \prod_{t=1}^{T} L_t = (2\pi)^{-\frac{NT}{2}} |\Sigma|^{-\frac{T}{2}} \exp \left( -\frac{1}{2} \sum_{t=1}^{T} e'_t \Sigma^{-1} e_t \right)$$

$$\propto |\Sigma|^{-\frac{T}{2}} \exp \left( -\frac{1}{2} \text{Tr} (\Sigma^{-1} S) \right), \quad \text{(A.11)}$$

where $S = \sum_{t=1}^{T} e_te'_t$ and we have used the fact that $e'_t \Sigma^{-1} e_t$ is a scalar (thus equal to its trace), and the properties of the trace operator.
We can now write the conditional distribution $\Sigma | \bar{\beta}, \bar{\gamma}$ as follows:

$$
f(\Sigma | \bar{\beta}, \bar{\gamma}) \propto f(\Sigma) L(\Sigma | \bar{\beta}, \bar{\gamma})$$

$$
\propto |\Sigma|^{-\frac{v_0N+1}{2}} \exp \left( -\frac{1}{2} \text{Tr} (\Phi_0 \Sigma^{-1}) \right) \times |\Sigma|^{-\frac{1}{2}} \exp \left( -\frac{1}{2} \text{Tr} (\Sigma^{-1} \Phi_0 + S) \right)
$$

which establishes $\Sigma | \bar{\beta}, \bar{\gamma} \sim IW(v_0 + T, \Phi_0 + S)$.

**Appendix B. Bayesian Variable Selection in SUR**

This section derives the conditional distributions required for our variable selection methodology using the Gibbs sampler. Let $X_\gamma$ represent the matrix $X$ where each column has been multiplied by the corresponding $\gamma_j$. Then we can write the model with variable selection as $r_i = X_\gamma \beta_i + e_i, i = 1, \ldots, N$. Stacking the $N$ equations, we can also represent the model as:

$$
\begin{bmatrix}
r_1 \\
r_2 \\
\vdots \\
r_N
\end{bmatrix}
= 
\begin{bmatrix}
X_\gamma & 0 & \cdots & 0 \\
0 & X_\gamma & \cdots & 0 \\
\vdots & \vdots & \ddots & \vdots \\
0 & 0 & \cdots & X_\gamma
\end{bmatrix}
\begin{bmatrix}
\beta_1 \\
\beta_2 \\
\vdots \\
\beta_N
\end{bmatrix}
+ 
\begin{bmatrix}
e_1 \\
e_2 \\
\vdots \\
e_N
\end{bmatrix}
$$

or

$$
\bar{r} = \bar{X}_\gamma \bar{\beta} + \bar{e}.
$$

Note that, conditional on $\gamma$, the model reduces to a SUR with the corresponding predictors for which $\gamma_j = 1$. Therefore, we can use the results derived in the previous section for $\bar{\beta}|\Sigma, \gamma, \bar{\gamma}$ and $\Sigma|\bar{\beta}, \gamma, \bar{\gamma}$, substituting $\bar{X}$ by $\bar{X}_\gamma$.

**Appendix B.1. Distribution of $\bar{\beta} | \Sigma, \gamma, \bar{\gamma}$**

Using the results from the previous section, treating $\Sigma$ and $\gamma$ as known, the posterior distribution of $\bar{\beta} | \Sigma, \gamma, \bar{\gamma}$ is $N(b_1, B_1)$, where

$$
b_1 = (B_0^{-1} + \bar{X}_\gamma' \Omega^{-1} \bar{X}_\gamma)^{-1}(B_0 b_0 + \bar{X}_\gamma' \Omega^{-1} \bar{e})
$$

$$
B_1 = (B_0^{-1} + \bar{X}_\gamma' \Omega^{-1} \bar{X}_\gamma)^{-1}
$$

We can also use the sequential generation of $\beta_i, i = 1, \ldots, N$ as in Section Appendix A.2. In this case, we rewrite the partition in equation A.7 in terms of
\(\tilde{X}_y\) and define \(\tilde{X}_{y,-i}\) as the matrix that collects the structure of \(\tilde{X}_y\) for the remaining \(N - 1\) equations. Then, assuming \(\gamma\) known, we have \(\beta_i|\tilde{\beta}_{-i}, \gamma, \Sigma, \tilde{r} \sim N(b_{1,i}, B_{1,i})\), with

\[
\begin{align*}
    r_i^* &= r_i - (\sigma^0)^{-1} A (\tilde{r}_{-i} - \tilde{X}_{y,-i} \tilde{\beta}_{-i}) \\
    B_{1,i} &= (B_{0,1}^{-1} + \sigma^i X'_{j} X_{j})^{-1} \\
    b_{1,i} &= (B_{0,i}^{-1} + \sigma^i X'_{j} X_{j})^{-1} (B_{0,i}^{-1} b_{0,i} + \sigma^i X' r_i^*).
\end{align*}
\]

**Appendix B.2. Distribution of \(\Sigma|\tilde{\beta}, \gamma, \tilde{r}\)**

Using the results from the previous section, treating \(\tilde{\beta}\) and \(\gamma\) as known, we have \(\Sigma|\tilde{\beta}, \gamma, \tilde{r} \sim IW(\nu_0 + T, \Phi_0 + S\gamma)\), where \(S\gamma\) is calculated using the residuals from equation B.1.

**Appendix B.3. Distribution of \(\gamma|\Sigma, \tilde{\beta}, \tilde{r}\)**

The simplest approach to generate \(\gamma|\Sigma, \tilde{\beta}, \tilde{r}\) is to use the Gibbs sampler to generate each value of \(\gamma\) component-wise, that is, we can generate each \(\gamma_j\), conditionally on the remaining \(\gamma_i, i \neq j\), which we denote as \(\gamma_{-j}\), \(\Sigma\), and \(\tilde{\beta}\). For a given \(j\), denote by \(L_{j,1} = L(\gamma_j = 1|\gamma_{-j}, \Sigma, \tilde{\beta}, \tilde{r})\) the likelihood function evaluated at \(\gamma_j = 1\), considering \(\gamma_{-j}, \Sigma\) and \(\tilde{\beta}\) known, and likewise by \(L_{j,0} = L(\gamma_j = 0|\gamma_{-j}, \Sigma, \tilde{\beta}, \tilde{r})\) the likelihood evaluated at \(\gamma_j = 0\). Then, using the fact that the prior distribution of the \(\gamma_j\) is \(B(1, \pi_j), j = 1, \ldots, N\), we have

\[
P(\gamma_j = 1|\gamma_{-j}, \Sigma, \tilde{\beta}, \tilde{r}) = \frac{\pi_j L_{j,1}}{\pi_j L_{j,1} + (1 - \pi_j)L_{j,0}}. \tag{B.2}
\]

Let \(\gamma_j^1\) and \(\gamma_j^0\) represent the vector \(\gamma\) with the \(j-th\) position fixed at 1 or 0, respectively. That is,

\[
\begin{align*}
    \gamma_j^1 &= [\gamma_1, \ldots, \gamma_{j-1}, 1, \gamma_{j+1} \ldots \gamma_K]', \\
    \gamma_j^0 &= [\gamma_1, \ldots, \gamma_{j-1}, 0, \gamma_{j+1} \ldots \gamma_K]'.
\end{align*}
\]

Further, let \(e_j^1\) and \(e_j^0\) represent the residuals, at observation \(t\), if \(\gamma_j = 1\) and if \(\gamma_j = 0\), respectively. Let \(S_{\gamma}^1\) and \(S_{\gamma}^0\) represent the corresponding residual matrices. Then we can write, using A.11:

\[
\begin{align*}
    L_{j,1} &= (2\pi)^{-\frac{\nu}{2}} |\Sigma|^{-\frac{1}{2}} \exp\left(-\frac{1}{2} \text{Tr}(\Sigma^{-1} S_{\gamma}^1)\right) \\
    L_{j,0} &= (2\pi)^{-\frac{\nu}{2}} |\Sigma|^{-\frac{1}{2}} \exp\left(-\frac{1}{2} \text{Tr}(\Sigma^{-1} S_{\gamma}^0)\right).
\end{align*}
\]
Substituting the above into B.2, we get

\[
P(\gamma_j = 1|\gamma_{-j}, \Sigma, \hat{\beta}, \hat{r}) = \frac{\pi_j \exp\left(-\frac{1}{2} \text{Tr} (\Sigma^{-1} S^j_0) \right)}{\pi_j \exp\left(-\frac{1}{2} \text{Tr} (\Sigma^{-1} S^j_1) \right) + (1 - \pi_j) \exp\left(-\frac{1}{2} \text{Tr} (\Sigma^{-1} S^0_0) \right)} + \left(1 + \frac{1 - \pi_j}{\pi_j} \exp\left[-\frac{1}{2} \text{Tr} (\Sigma^{-1}(S^j_1 - S^0_1)) \right]\right)^{-1},
\]

where we have taken the inverse of the expression on the right-hand side twice.

**Appendix C. Factor Construction**

[Table 9 about here.]
Table C.9: The Factor Zoo: candidate factors/firm characteristics

The table lists the 82 firm characteristics used to construct tradable factors.
